

150-WORD NON-TECHNICAL SUMMARY

A penetration test was performed to measure the security of the organization's systems in a controlled manner. The testing simulated real cyber-attacks that criminals commonly attempt, including web attacks, API misuse, network exploitation, and privilege escalation. The goal was to identify weaknesses before attackers can abuse them.

During the assessment, several outdated services and insecure components were found, such as vulnerable FTP, SMB, and API endpoints. These weaknesses allowed unauthorized access, data exposure, and potential full system compromise. Tests also showed that attackers could escalate privileges, intercept unencrypted traffic, and modify system behavior.

No real damage was done during the assessment. Instead, evidence was collected to demonstrate risks and help prioritize security improvements. The test concluded that the current environment requires immediate patching, stronger access control, and better monitoring. Implementing the recommended remediation steps will significantly increase resilience against real-world cyber threats.
